NEW RECORDS OF FOSSIL VERTEBRATES FROM THE UPPER CRETACEOUS ADAMANTINA FORMATION (BAURU GROUP), SOUTHEASTERN BRAZIL

Caio Fabricio Cezar GEROTO
Reinaldo José BERTINI

ABSTRACT

The Adamantina Formation (Bauru Group), between Lucélia and Irapuru municipalities (northwestern São Paulo State, southeastern Brazil), has been in the last years a very important area for collecting Upper Cretaceous fossil vertebrates. So far, the main groups recovered include Testudines, Crocodyliformes and Dinosauria (Theropoda and Titanosauria). The fossil material is usually disarticulated and fragmented and was collected from very fine-grained sandstones, with muddy matrix and cross-stratification and lamination. Testudines are represented by fragments of carapaces and plastrons. Crocodyliformes are composed only of fragmented osteological remains and isolated teeth. Maniraptora is especially represented by isolated teeth, allowing the identification of the Dromaeosaurinae, Velociraptorinae and Troodontidae clades, in addition to some probable endemic groups. Titanosauria is the most representative and abundant group in these fossil localities, however materials are mainly fragments of ribs and some appendicular bones, without diagnostic osteological elements, like caudal vertebrae. The lithological characteristics of the outcrops suggest a paleoenvironment of braided rivers, in an arid climate, with few vegetation cover.

Keywords: Bauru Group, Adamantina Formation, São Paulo State, Maniraptora, Titanosauria.

RESUMO

NOVOS REGISTROS DE VERTEBRADOS FÓSSEIS DO CRETÁCEO SUPERIOR NA FORMAÇÃO ADAMANTINA (GRUPO BAURU), SUDESTE DO BRASIL. A Formação Adamantina (Grupo Bauru), entre os municípios de Lucélia e Irapuru (nordeste do Estado de São Paulo, sudeste do Brasil), tem sido nos últimos anos uma região muito importante para a prospecção de vertebrados fósseis do Cretáceo Superior. Até agora os principais grupos recuperados incluem Testudinos, Crocodyliformes e Dinosauria (Theropoda e Titanosauria). Os materiais são normalmente desarticulados e fragmentados e foram coletados em arenitos de granulação muito fina com matriz lamítica, com estratificações e laminações cruzadas. Testudinos são representados por fragmentos de carapaças e plastrões, enquanto Crocodyliformes, por restos osteológicos fragmentados e dentes isolados. Maniraptora é representado por dentes isolados, que permitiram a identificação dos clados Dromaeosaurinae, Velociraptorinae e Troodontidae, além de alguns prováveis grupos endêmicos. Titanosauria é o agrupamento mais expressivo e abundante nestas localidades, contudo os materiais são principalmente costelas fragmentadas e ossos apendiculares, sem elementos diagnósticos, como vértebras caudais. As características litológicas dos afloramentos sugerem um paleoambiente de rios entrelaçados em clima árido e possivelmente com pouca cobertura de vegetação.

Palavras-chave: Grupo Bauru, Formação Adamantina, Estado de São Paulo, Maniraptora, Titanosauria.
1 INTRODUCTION

The Adamantina Formation (Bauru Group) is the most widespread sequence of continental sedimentary deposits of the Upper Cretaceous from southeastern Brazil. It outcrops in northwestern São Paulo State, between Lucélia and Irapuru municipalities. During the last twenty years, this area has been important for excavation and study of fossil vertebrates, increasing the knowledge about lithofacies and fossil assemblages (BERTINI 1993, SANTUCCI 1999). In the last twelve years, some new fossil localities with additional material were found (ANDRADE 2002).

The main vertebrate groups found in the area belong to Testudines, Crocodyliformes and Dinosauria (Theropoda and Sauropoda). The material is mostly fragmentary and well preserved, and complete elements are scarce. Testudines are represented by fragments of carapaces and plastrons. Crocodyliformes are represented by isolated teeth, as well as Maniraptora. Titanosauria are mainly represented by appendicular remains.

The paleofauna from northwestern São Paulo State was reported in previous studies (BERTINI 1993, BERTINI et al. 1997, FRANCO & BERTINI 1997, ANDRADE 2002, SANTUCCI & BERTINI 2006, ANDRADE & BERTINI 2008). These authors proposed the existence of some endemism, but also the presence of animals with a wide paleobiogeographic distribution, inhabiting other regions of the Upper Cretaceous of South America (SANTUCCI 2002).

Because of the importance of this region in the excavation and study of fossil vertebrates, collective efforts have been made in the last years, leading to discoveries of new localities and materials. The main objective of this study is to examine and describe specimens collected until now.

2 MATERIALS AND METHODS

The specimens described in this study were collected in an area 20 km around Florida Paulista City (Figure 1), between Lucélia e Irapuru municipalities, and are housed in the collection of the “Grupo de Ciências Luckesi”, located in “Escola Estadual José Firpo”, Lucélia City, São Paulo State. A considerable number of fossils have been collected by local people, who unfortunately did not gather information about the precise location of the outcrops. Therefore, these fossils cannot be associated with any fossil locality reported by ANDRADE (2002). Fossil prospecting and collecting were not organized and outcrop locations are usually unknown.

There are 34 recognized outcrops in the investigated area, characterized by very fine-grained sandstones associated with sandy conglomerates. Six new fossil localities were identified during the field trips, consisting of 40 collecting sites (Figure 1, Table 1). The numbers of the new outcrops follow the list displayed by ANDRADE (2002), since they are located in the same region. In five of these sites, a large amount of fragmented fossils were found, supporting future fossil prospecting. For instance, four ribs, a pubis and an ischium of titanosaurians described in this paper were found in site 40. This locality is situated in a vicinal road close to Santana Farm, showing massive or laminated (parallel stratification) very fine beige sandstones, with sub-rounded to sub-angular grains, a strong silty matrix, and carbonate cementation.

The nomenclature used for Testudines and Crocodylomorpha fossils is based on ROMER (1997). Descriptions of the titanosaurians specimens are accompanied by measurements, according to the nomenclature used by WILSON (1999) and POWELL (2003). After mechanical preparation, the specimens were identified by comparison with other materials, based mainly on the literature (CURRIE et al. 1990, FRANCO 1999, WILSON 1999, POWELL 2003, ANDRADE 2005, PINHEIRO 2007) and occasional consultation to collections of UNESP Rio Claro, “Departamento Nacional da Produção Mineral” from Rio de Janeiro, “Centro de Pesquisas Paleontológicas Llewellyn Ivor Price” from Uberaba and “Museu Paleontológico de Monte Alto”.

List of abbreviations follow FRANCO (1999) and POWELL (2003): A.art.: width of the articular surface; Ad.: maximum distal width; Am.: minimum width; Amed.: width between medial borders; Ap.: maximum proximal width; Ap.lt.: lateral apophyses; B: basal length of the tooth; BP: keel inclination of the tooth, related to base; Cc.: cnemial crest; Co.br.: area of attachment of the coracobrachial muscle; C. med.: medial condyle; Cr. Dlepc.: deltopectoral crest; DPM: denticles per millimeter of the tooth keel; F.: foramen; FABL: basal transversal section diagram of the tooth;
FIGURE 1 – Map of fossiliferous outcrops between Lucélia and Irapuru municipalities, northwestern São Paulo State (Modified from ANDRADE 2002). Sites 1 to 40 are outcrop localities of BERTINI (1993), SANTUCCI (1999), ANDRADE (2002) and GEROTO (2010).

3 GEOLOGICAL ASPECTS

Although, in recent years, there has been intense debate about the validity of the term Bauru “Basin”, this is beyond the scope of this contribution. Even some geologists (MILANI 1997; PAULA E SILVA et al. 2003, 2005; STRADIO et al. 2008) still prefer to consider these deposits (Bauru Group) as belonging to the Paraná Basin, which covers an area of about 350,000 km² and outcrops in Goiás, Mato Grosso do Sul, Minas Gerais, São Paulo and Paraná states (FERNANDES & COIMBRA 2000). The Bauru Group comprises a sedimentary sequence outcropping mainly in Western São Paulo State (PAULA E SILVA 2003). It overlies mainly the basaltic rocks of the Serra Geral Formation, and locally the deposits of the Botucatu and Piramboia formations (PAULA E SILVA & CAVAGUTTI 1994).

The stratigraphic division adopted in this paper is based on proposals from SOARES et al. (1980), BATEZELLI (1998), FERNANDES (1992) and PAULA E SILVA (2003). Therefore, in the São Paulo State, the Bauru Group is divided into Caiuá, Pirapozinho, Santo Anastácio, Birigui, Araçatuba, Adamantina and Marília formations.

This study accepts ages ranging from Upper Campanian to Lower Maastrichtian for the Adamantina Formation, based on assumptions of BERTINI et al. (2000), BERTINI & SANTUCCI (2001), BERTINI & MENEGAZZO (2009).

The study area is situated between Lucélia and Irapuru municipalities, Southwestern São Paulo State, showing outcrops of the Adamantina Formation (Figure 1). It is the most widespread geological unit in this region, which was identified along the ridges among rivers, with a thickness of about 190 m (SOARES et al. 1980).

This geological unit is distinguished from other formations of the Bauru Group by lithofacies changes, which allows many paleoenvironmental interpretations (SOARES et al. 1980). It is usually characterized by fine grained sandstones, pink to brown in color, with cross-stratifications, alternating with mudstones and siltstones, red to gray in color, sometimes massive or laminated (with parallel stratifications), with common ripple marks and cross-laminated stratification.

4 PRELIMINARY RESULTS

4.1 Testudines / LF - 122 - R

The materials assigned to Testudines, including many remains of carapaces and plastrons, are not diagnostic for a classification, with the exception of a fragment of right xiphiplastron (Table 2), presenting fragmented portions of the pelvis.

4.2 Crocodylomorpha

LF - 123 - R is a fragment of an indeterminate crocodyliform skull, showing ornamentation of large and deep oval pits, characteristic of some Crocodylomorpha taxons, like Itasuchus jesuinoi and Pepeusuchus deiseae (PRICE 1955, CAMPOS et al. 2011).

LF - 124 - R is morphologically similar to a Baurusuchidae surangular, showing a dorsal curvature and the glenoid fossa with a posterior edge forming a ridge. Both characteristics are present in the surangular of Baurusuchus pachecoi PRICE, 1945 (DGM 299-R) and Baurusuchus salgadoensis CARVALHO et al., 2005 (MPMA 62-0001-02).

LF - 125 - R corresponds to a long proximal epiphysis of a tibia, which probably corresponds to articulation of the femoral condyles, belonging to Crocodyliformes. The diaphyseal diameter (Table 2) and two articular points, a dorsally flat elongated protuberance and another more laterally displaced one are similar to the proximal epiphysis of a tibia related to Baurusuchus salgadoensis specimens UFRJ 282-R and UFRJ 417-R.

4.3 Maniraptora

Maniraptora fossils are frequently fragmentary and not diagnostic. They include an epiphysis of appendicular bone, four probable diaphyses, and a controversial fragment of skull. The appendicular elements are slender and similar to Austroraptor cabazai NOVAS et al., 2009 (GIANECHINI & APESTEGUIA 2011).

However, in the outcrops between Lucélia and Irapuru cities, Maniraptora teeth (Table 3) are the most expressive elements associated with this group, and are mainly represented by isolated elements. Fourteen isolated specimens were identified and described, according to CURRIE et al. (1990) and FRANCO (1999).

4.3.1 Tooth / Velociraptorinae / LF - 016 - R

This tooth is laterally compressed, with elliptical root shape. The denticles are high, with accentuated interdentine slits, and rounded tops ending in hook shapes (Figure 2A). Inclination of the keel to the base, number of denticles per millimeter, morphological class of denticles (Table 3), and flattening of the lingual face are
### TABLE 2 – Fossil material identified for each taxon.

**4.3.2 Tooth / Velociraptorinae / LF - 021 - R**

This tooth is laterally flattened. The anterior keel denticles are more worn than the posterior ones, which is a characteristic of Velociraptorinae. The inclination of the keel (Table 3) to the base of the tooth is similar to the specimens 81 SA and 108 SA, described by FRANCO (1999). The denticles are high, with rounded tops, and assigned to Class 1.2 from CURRIE et al. (1990), related to Velociraptorinae. The interdentine slits are accentuated (Figure 2F).
FIGURE 2 – Maniraptora teeth, left columns teeth photographs, right columns FABL schemes: (A) LF - 016 - R, lingual view (left), FABL (right); (B) LF - 017 - R, labial view (left), FABL (right); (C) LF - 018 - R, lingual view (left), FABL (right); (D) LF - 019 - R (labial view), FABL (right); (E) LF - 020 - R, labial view (left), FABL (right); (F) LF - 021 - R, lingual view (left), FABL (right); (G) LF - 022 - R, labial view (left), FABL (right); (H) LF - 023 - R, lingual view (left), FABL (right); (I) LF - 024 - R, lingual view (left), FABL (right); (J) LF - 025 - R, lingual view (left), FABL (right); (K) LF - 026 - R, lingual view (left), FABL (right); (L) LF - 027 - R, lingual view (left), FABL (right); (M) LF - 028 - R, lingual view; (N) V 17, lingual view (left), FABL (right). Scale bars: 10 mm.
Total height of the tooth (Table 3) is similar to values measured for the Velociraptorinae teeth described by FRANCO (1999) in the Adamantina Formation. The diagram of the basal cross-section (Figure 2) is similar to the specimen 108 AS, which was described by FRANCO (1999).

4.3.3 Tooth / Velociraptorinae / LF - 022 - R

The tooth is elongated and flattened on the lingual face, and denticles are high, curved on the tops. The basal cross-section (Figure 2G) is similar to the specimens from FRANCO (1999), which are associated with Velociraptorinae. The total height, inclination of the keel to the base, and denticles per millimeter (Table 3) for this tooth are similar to teeth described by the same author for the Velociraptorinae, which corroborates this association.

4.3.4 Tooth / Dromaeosaurinae / LF - 17 - R

This tooth has an elliptical base (Figure 2B). The apex is preserved. The denticles are associated with Class 2 from CURRIE et al. (1990), indicating it could be a Dromaeosaurinae tooth, which can be corroborated by the morphology of the basal cross-section, number of denticles per millimeter, inclination of the keel to the base, and total height (Table 3), all characteristics shared with the teeth of Dromaeosaurinae described by FRANCO (1999). The posterior keel denticles are high, slightly curved, with deep interdentine slits. The top of the denticles is chisel-like.

4.3.5 Tooth / Dromaeosaurinae / LF - 018 - R

This tooth has an elliptical base (Figure 2C). The denticles are high and closed spaced and their top are chisel-like and the interdentine slits are deep (Figure 2C). The denticles on the posterior keel are point-shaped and not rounded, and, therefore, it could be associated with Class 2 from CURRIE et al. (1990). Total height, inclination of the keel to the base, and denticles per millimeter (Table 3) are characteristics shared by Troodontidae and Dromaeosaurinae teeth, as proposed and described by FRANCO (1999). The diagram of the basal cross-section (Figure 2C) is associated with Morphology 2 from FRANCO (1999), also present in Dromaeosaurinae and Troodontidae. However, the wear pattern of denticles is typical of Dromaeosaurinae. Consequently, it is preferable to associate this tooth with this last group.
4.3.6 Tooth / Dromaeosaurinae / LF - 024 - R

The inclination of the keel to the base is similar to that of 6 I and 7 I, specimens described by FRANCO (1999). The denticles are high and well developed in lingual view, with apparently chisel-like tops and accentuated interdentine slits (Figure 2I). This set of characteristics is assigned to Class 2 from CURRIE et al. (1990), which is related to Dromaeosaurinae.

4.3.7 Tooth Dromaeosauridae / LF - 027 - R

This tooth is labio-lingually flattened (Figure 2L). The denticles are high, with chisel-like top and deep interdentine slits. It can be associated with Class 2 from CURRIE et al. (1990). The total height (Table 3) is close to that of other teeth assigned to Dromaeosaurinae.

4.3.8 Tooth / Troodontidae / LF - 019 - R

This tooth has an elliptical base and longitudinal grooves, and is quite laminar (Figure 2D). The denticles are high and have rounded tops, and the interdentine slits are deep and accentuated. The number of denticles per millimeter (Table 3) is associated with Class 1.1 from CURRIE et al. (1990). It is a Troodontidae tooth, which has characteristics similar to many Troodontidae specimens described by FRANCO (1999), such as diagram of the basal cross-section and inclination of the keel (Table 3) to the base (90°).

4.3.9 Tooth Troodontidae / LF - 020 - R

This is a laterally flattened tooth. The denticles are high, with flap tops, and the interdentine slits are deep and accentuated (Figure 2E). It shares general features, such as total height, number of denticles per millimeter, inclination of the keel to the base and diagram of the basal cross-section, (Table 3) with specimens assigned to Troodontidae by FRANCO (1999).

4.3.10 Tooth / Troodontidae / LF - 023 - R

This tooth is laminar and more laterally flattened than other teeth of this assemblage, with the posterior keel straight and the anterior one curved near the apex (Figure 2H). The denticles are rounded on top, with marked interdentine slits. The general design is the same of the Class 1.1 from CURRIE et al. (1990). Such morphology was also associated by FRANCO (1999) with Troodontidae. Total height, inclination of the keel to the base, number of denticles per millimeter, and diagram of the basal cross-section (Table 3) are similar to the characteristics defined by FRANCO (1999) for this group.

4.3.11 Tooth / Troodontidae / LF - 026 - R

It is a laminar tooth (Figure 2K); denticles are high and rounded on top, with deep interdentine slits. The general design associates it with Class 1.1 from CURRIE et al. (1990). Denticles per millimeter, diagram of the basal cross-section, and total height (Table 3) seem to indicate that it is a Troodontidae tooth.

4.3.12 Tooth / Troodontidae (?) / V 17

This tooth (Figure 2N) has high denticles, with rounded tops, and accentuated interdentine slits, and was identified as belonging to Class 1.1 from CURRIE et al. (1990). Tooth height and diagram of the basal cross-section are similar to values measured for specimens 3 I and 122 CPP from FRANCO (1999), both showing approximate values of TCH (Table 3). When compared to 3 I and 122 CPP, values of inclination of the keel to the base and number of denticles per millimeter (Table 3) are identical to equivalents from V 17.

It is a laminar tooth; the inclination of the keel to the base is 90° (Table 3). The similarities between LF - 025 - R and the equivalent teeth described by FRANCO (1999) include significant wear facets of the keels, and general morphology and diagram of the basal cross-section (Figure 2J), but LF - 025 - R is bigger in size. Considering these characteristics, this tooth was assigned to Taxonomic Group B of FRANCO (1999).

4.3.14 Tooth / Taxonomic Group C from FRANCO (1999) / LF - 028 - R

The tooth is less labio-lingually flattened than the previous one (Figure 2M). The denticles are short, with equivalent height and width, deep interdentine slits and chisel-like tops. Therefore, it can be assigned to Class 3 proposed by FRANCO (1999). The total height (Table 3) is 1 cm, higher than the biggest Dromaeosaurinae tooth described by FRANCO (1999). This tooth has 4 denticles per millimeter (Table 3), and, according to FRANCO (1999), no other Dromaeosaurinae tooth has this
number of denticles. The measurements of the keel inclination to the base and the number of denticles per millimeter are similar to those of teeth associated with the Taxonomic Group C of FRANCO (1999).

4.4 Titanosauria

This group is very abundant in the study area, with diverse isolated and fragmentary vertebrae and ribs, as well as appendicular elements. But unfortunately they are not diagnostic (Table 4).

4.4.1 Dorsal Vertebrae / Titanosauria / LF - 007 - R

This is an opisthocoelic dorsal vertebra, assigned to Titanosauria due to the presence of well-developed pleurocoels and laminae, and considered synapomorphies of the group (WILSON 2002) (Table 4). Only the posterior region and part of the vertebral centrum were preserved. The most anterior portion of the vertebrae is absent, with very damaged laminae (Figure 3).

FIGURE 3 – LF - 007 - R, caudal vertebrae, left lateral view (left); right lateral view (right). Scale in centimeters.
The posterior articular surface is ventrally deformed, and one margin is longer than the other, like *Saltasaurus loricatus*. Pre- and postzygapophyses are fragmented on their ends and the anterior articulation surface is absent. The neural canal measures 55 mm in length and 35 mm in diameter. It is not possible to visualize any of the transverse processes. However, it is possible to observe their positions, and all are above the vertebral centrum.

The postzygapophyses are posteriorly inclined and almost parallel to the vertebral centrum, which was caused by deformation during fossilization. The posterior centroparapophysial lamina is present on the right lateral face, but is fragmented on the left one (Figure 3).

The posterior centroparapophysial lamina is present on both faces of the vertebral centrum, with a foramen on the base. The suprapostzygapophysial lamina is fragmented and almost absent, as well as the transverse processes (Figure 3). In anterior view, it is similar to a medium dorsal vertebrae of *Saltasaurus loricatus* (POWELL 2003).

4.4.2 Caudal Vertebrae / Titanosauria / LF - 008 - R

It is a centrum of procoelic caudal vertebrae, with a large socket on the anterior articulation surface and a ball on the posterior articulation surface, which are characteristics of Titanosauria vertebrae (POWELL 2003). The diameter of the center is similar to values measured by POWELL (2003) for a great number of Titanosauria (Table 4). It is not possible to observe many structures in the specimen, only the central portion of the neural arch (Figure 4B), but the morphology is identical to that of a caudal vertebrae of *Uberabatitan riberoi* SALGADO & CARVALHO, 2008 (CPP 1009-UrHO, CPP 1010-UrHO, CPP 1008-UrB).

4.4.3 Centrum of Vertebrae / Titanosauria / LF - 009 - R

A centrum of vertebrae (Table 4) without significant structures was preserved. There is only evidence of the neural arch, which is slightly central-laterally flattened and more dorso-ventrally flattened, creating semi-plane surfaces (Figure 4A). Its similarity with Titanosauria vertebrae is supported by morphological comparison with the caudal vertebrae of titanosaurians described by POWELL (2003).

4.4.4 Right Pubis / Titanosauria / LF - 011 - R

This was identified as the proximal portion of a right pubis of Titanosauria (Table 4). It is possible to observe an open obturator foramen in the anterior region of the pubis (Figure 5). In addition, there is a prominent curve, which seems to have some continuity, but is absent in the distal part of the specimen. The position of these morphological elements is similar to that shown in figures of a *Camarasaurus* pubis from WILSON & SERENO (1998). Therefore, the reconstruction of the specimen was based on that genus.

4.4.5 Right Ischium / Titanosauria / LF - 012 - R

The specimen, which is very damaged, was associated with LF - 011 - R (Table 4). Below the

FIGURE 4 – (A) LF - 009 - R, centrum of caudal vertebrae, right lateral view; (B) LF - 008 - R, centrum of caudal vertebrae, right lateral view. Scale in centimeters.
There is a depression, which is also present in the rest of the specimen. There is an entry at the beginning of this lamina, forming a right angle. The superior and inferior portions of this lamina do not show evidence of fragmentation or indications of articulation points. Due to morphological similarities with an ischium of *Aeolosaurus rionegrinus* described by Powell (2003), it can be referred to as an ischium lamina (Figure 6).

4.4.6 Ribs / Titanosauria

Four ribs (Figure 7A-D) were collected from the study area, three of them (LF - 1V, LF - 2V and LF - 3V) were associated with LF - 011 - R and LF - 012 - R from Santana Farm, Locality 40 (Table 1), Flórida Paulista City. The ribs are long and robust, similarly to titanosaurian equivalents described by Wilson (2002).

- LF - 1V (Table 4) is damaged, fragmented in many pieces, with no epiphyses.
- LF - 2V (Table 4) has many fracture points, but the proximal epiphysis and the articulation region of the vertebrae are preserved, the latter as a bifurcate arch, with one of the extremities absent and the other showing some extension. This rib is thicker than other two collected from the same locality, showing minor differences in length.
- LF - 3V (Table 4) preserves a fragment of the proximal epiphysis, and the distal epiphysis is absent. The width is constant, increasing after the preserved area, and becoming more flattened.
- LF - 4V (Table 4) is slightly curved in length, very fragmented, consisting only of the diaphysis, lacking proximal epiphysis, articulation area for the vertebrae, and distal diaphysis.

4.4.7 Left Humerus / Titanosauria LF - 002 - R

This humerus (Table 4) is associated with this group due to its square latero-dorsal corner, which is a characteristic of titanosaurs (Figure 8 A-B) (Powell 2003). The specimen is damaged along its length, with fissures. Parts of the proximal epiphysis and the diaphysis were repaired with Plaster of Paris. The margin of the posterior concavity of the proximal epiphysis is less prominent, progressively joining the humerus diaphysis.

In anterior view, the area for insertion of the *coracobrachialis* muscle is broken. The region between the *coracobrachialis* muscle and the superior
portion of the proximal epiphysis is concave, long, and shallow. The deltopectoral crest is more prominent when compared to *Saltasaurus* (BONAPARTE & POWELL 1980), and its morphology is more similar to the morphology observed in *Argyrosaurus* (POWELL 2003), but it does not reach the external margin of the anterior face.

The posterior face of the distal epiphysis is damaged up to the region of the radius / ulna articulation. On the anterior face of the distal epiphysis, it is possible to observe a small lamina, extending to its end. Although fragmented, this lamina (L.h. in the Figure 8) measures 100 mm in length and at least 20 mm in height in its highest point.

4.4.8 Right Humerus / Titanosauria / LF - 001 - R

The maximum length and cross-section of the diaphysis may not be correct because the present specimen was fragmented (Table 4). It was subsequently restored, but the point of break in the diaphysis is still visible in the images (Figures 8C-D).

The *coracobrachialis* fossa is very pronounced and well-demarcated (Figure 8C), as well as short and deep, similarly to *Saltasaurus* (BONAPARTE & POWELL 1980). The square laterodorsal region and the dimensions associate this right humerus with Titanosauria.

FIGURE 7 – Titanosauria ribs: (A) LF - 1V; (B) LF - 2V; (C) LF - 3V; (D) LF - 4V. Scale in centimeters.

FIGURE 8 – LF - 002 - R, left humerus, (A) anterior view, (B) posterior view. LF - 001 - R, right humerus, (C) anterior view, (D) posterior view. Scale in centimeters.
The deltopectoral crest is well preserved and developed and aligned to the antero-lateral margin of the humerus. The area for attachment of the coracobrachialis muscle is also intact and very prominent. The anterior and posterior faces of the proximal epiphysis are slightly damaged. The diaphysis is completely broken, dividing the humerus into two parts. The distal epiphysis is well preserved, with both radial and ulnar condyles slightly damaged. There is a lamina (L.h. in the Figure 8) in the anterior region of the distal epiphysis, next to the condyle of the radius articulation, measuring 110 mm in length and 20 mm in height.

4.4.9 Left Humerus / Titanosauria / LF - 006 - R

This specimen has the same morphology of LF - 002 - R, which makes it possible to identify it as a left humerus of Titanosauria. The material is fragmented, and its identification was possible by examining the well-demarcated inferior margin of the coracobrachialis fossa (ROMER 1997, POWELL 2003) and by analyzing its dimensions (Figure 9). Despite fragmentation, the absence of both epiphysis and its dimensions suggest it was a robust bone (Table 4).

It is possible to observe part of the deltopectoral crest and part of the coracobrachialis fossa, allowing the identification of the anterior view (Figure 9). The specimen is antero-posteriorly flattened, and in antero-posterior view, its external border is straighter than the internal one, which is concave, indicating it would be a left humerus.

4.4.10 Right Femur / Titanosauria / LF - 003 - R

This is an antero-posteriorly flattened (Figure 10) long bone (Table 4), with a typical morphology of a femur of sauropod (CARRANO 2005) and a bigger trochanter parallel to the femoral condyle, which makes it possible to identify it as a titanosaur femur (UPCHURCH et al. 2007). The identification was made comparing it with the femur of Saltasaurus loricatus (POWELL 2003; Plate 44).

In anterior view, (Figure 10) the femoral condyle extends to the left medial portion of the bone, indicating it is a right femur. It is broken into three parts. Unfortunately, some complementary fragments from these fractured areas are missing.

4.4.11 Right Tibia / Titanosauria / LF - 005 - R

It is a proximal epiphysis of an appendicular bone, possibly a right tibia (Table 4). Its shape and characteristics are similar to those of a Titanosaurus right tibia, when compared to figures of Plate 5, page 98, and Plate 12, page 105, from POWELL (2003). On the posterior face, it is possible to observe the articulation area to the femoral condyles. The cnemial crest is preserved, although there are some small fractures. The depression in the posterior region of the cnemial crest is prominent (Figure 11).
5 DISCUSSION AND CONCLUSIONS

The fossil-bearing layers are composed mainly of very fine-grained sandstones, with muddy matrix and cross- and parallel stratifications and laminations. It is possible to observe that the sedimentary facies of the Adamantina Formation show cyclicity, with alternating humid and arid seasons.

The fossil material comprises diverse fragments of Testudines, Crocodylomorpha, Maniraptora, and Titanosauria, the last two being the most significant. Much of the material found in the area is fragmented in small pieces. Some fossils are disarticulated, few are associated with other bones and/or articulated. Diagenetic reasons can be the cause of fragmentation of some fossils.

Some fossils show evidence of transport, such as the vertebral centra LF - 008 - R and LF - 009 - R. Other materials show evidence of deformation during diagenesis, like the dorsal vertebrae LF - 007 - R, which is antero-dorsally flattened. Other fossils show evidence of reworking and weathering after diagenesis, such as LF - 006 - R, LF - 011 - R, LF - 012 - R, LF - 1V, LF - 2V, LF - 3V and LF - 4V.

Fragments of turtles and crocodyliformes also show signs of weathering. Appendicular bones with abraded extremities of epiphyseal and Maniraptora teeth with broken roots were also collected in the study area.

This kind of preservation supports interpretations like prolonged exposure in a semi-arid and warm paleoenvironment (FERNANDES 1998). Since most bone remains are disarticulated and even displaced, separated by some distance, one possible explanation is the transport of the material, possibly with long exposure, from death to burial (HOLZ & SIMÕES 2002).

The fragmentation of other fossils could be caused by weathering, since some bones do not show typical helical fractures, indicating exposure before burial. The fractures are mainly transverse, suggesting there was breakage while they were embedded in sedimentary rock.

Some of the Titanosauria elements (LF - 003 - R, LF - 005 - R, LF - 007 - R, LF - 008 - R, LF - 009 - R, LF - 010 - R, LF - 1V - R, LF - 2V - R, LF - 3V - R, LF - 4V - R) have a whitish color, probably a result of calcium carbonate concentration in paleoenvironments, during fossilization. It is not common for materials from the outcrops of the Adamantina Formation around Flória Paulista Municipality. Future studies can evaluate, using thin sections of the material, if there was some kind of structural modification in these bone remains.

The clade Titanosauria is represented by some axial and appendicular remains. In the Bauru Group, six species were described: Gondwanattian faustoi KELLNER & AZEVEDO, 1999, Trigonosaurus pricei CAMPOS et al., 2005, Baurutitan britoi KELLNER et al., 2005, Adamantisaurus mezzalirai SANTUCCI & BERTINI, 2006, Uberabatitan ribeiroi SALGADO & CARVALHO, 2008 and Aeolosaurus maximus SANTUCCI & ARRUDA-CAMPOS, 2011.

Evidence collected from the study area regarding titanosaurian does not provide morphological indication for the identification of specific morphotypes. Taxonomic classification for this group was based on well-preserved vertebrae, with diagnostic anatomical/morphological elements. The axial elements are fragmented, with no significant morphological features.

The best preserved titanosaurian specimens are appendicular bones, ribs, remains of pelvic girdles, which do not provide morphological evidence for comparison. It is not possible to relate any of the Titanosauria remains to Adamantisaurus mezzalirai (SANTUCCI & BERTINI 2006), the only titanosaurid taxon described from the region until now.

LF - 007 - R is a fragmented opisthocoelic dorsal vertebrae, with some characteristics similar to Saltasaurus loricatus (POWELL 2003). LF - 002 - R is a left humerus, showing affinities with the equivalent of Argyrosaurus superbus (POWELL 2003). LF - 012 - R is an ischium with close affinities to Aeolosaurus rionegrinus. However, it is not possible to establish a relationship between them, and these morphotypes belong to an assemblage considered Upper Campanian / Early Maastrichtian in age (BONAPARTE & POWELL 1980, BONAPARTE et al. 1984, UPCHURCH et al. 2007).
The possible presence of *Aeolosaurus maximus* in the deposits of the Adamantina Formation shows its chronological importance, due to correlation with occurrences of this genus in Argentina, whose remains are found with hadrosaurs, indicating Campanian to Maastrichtian age for those localities, interpreted as a result of landmass connection between North and South America in this time interval (POWELL 1987, BONAPARTE 1992, SALGADO et al. 1997, SANTUCI & ARRUDA-CAMPOS 2011).

The material associated with Maniraptora is mainly represented by teeth. According to CURRIE et al. (1990) and FRANCO (1999), they can be assigned to Dromaeosaurinae, Velociraptorinae and Troodontidae, as well as to some endemic taxonomic groups from the Bauru Group.

Until now, the only records of Maniraptora dinosaurs from the Bauru Group are teeth, an ungual phalanx (NOVAS et al. 2005) and an opisthocoelic vertebra associated with Unenlagiidae (CANDEIRO et al. 2012), a subfamily of Dromaeosauridae, with representatives in Argentina and Madagascar (GIANECHINI & APESTEGUIA 2011). In Brazil, other Velociraptorinae representatives are found only in the Middle Cretaceous of the São-Luis Grajaú Basin (ELIAS et al. 2007).

FRANCO (1999) assumed that Maniraptora teeth from the Bauru Group, Adamantina and Marília formations, are mainly associated with Dromaeosaurinae, Velociraptorinae and Troodontidae. Teeth of Dromaeosaurinae, Velociraptorinae and Troodontidae from the Judith River Formation were interpreted as Campanian in age by CURRIE et al. (1990).

The same groups of Maniraptora and Titanosauria are identified in the study area. Based on biochronological data about these Maniraptora in North America and Titanosauria in Argentina, these deposits could be interpreted as Campanian - Maastrichtian in age. Furthermore, the presence of Dromaeosaurinae, Velociraptorinae and Troodontidae in North and South American deposits corroborates the hypothesis of a landmass bridge between these two continents in Campanian-Maastrichtian interval.

ACKNOWLEDGEMENTS

This research was supported by CNPq (401795 / 2010 – 1). The authors would like to thank M.Sc. Paulo Sérgio Fiorato for providing access to material for analysis and all students of the “Grupo de Ciências Luckesi” for their dedication in collecting and preparing some of these fossils. They are also grateful to Leila Rangel da Silva for taking pictures during her free time and to the anonymous reviewers, whose comments and suggestions greatly improved this paper.
